

Phellinus noxius

System: Terrestrial

Kingdom	Phylum	Class	Order	Family
Fungi	Eumycota	Hymenomycetidae	Aphylliphorales	Hymenochaetaceae

Common name limu mea (Samoan, Samoan Archipelago), brown root rot (English, worldwide)

Synonym *Fomes noxius*, Corner, 1932

Similar species *Phellinus lamaensis*

Summary Root and crown rot caused by *Phellinus noxius* is pantropical in distribution. Also known as brown root rot disease, it is present in native forests but most often noticed in disturbed areas. It has a broad host range and causes major losses in timber and hardwood plantations, agroforests and landscapes. The fungus forms an infection centre and spreads from tree to tree by root contact. It can exist on decaying roots in the soil for more than 10 years.

[view this species on IUCN Red List](#)

Species Description

A thick, dark brown to black crust forming around infected roots and lower stems is diagnostic for brown root rot disease. Decayed wood is white and reddish-brown to black strands are usually seen near the surface. Conks occasionally grow from the crust, are brown to black on the upper surface and gray-brown on the lower, or spore-forming surface.

The mycelial crust that forms around infected roots and lower stems is diagnostic for *P. noxius*. Mycelium is present between the bark and sapwood. Decayed wood is white, soft and crumbly, laced with reddish strands of hyphae that turn black with age. Fruiting bodies may grow from the crust and are effused, effused-reflexed, or resupinate. They are brown to black and rough on the sterile surface, gray to gray-brown on the fertile surface (Brooks, 2002b).

Lifecycle Stages

The main vegetative stage of *P. noxius* is a dikaryotic mycelium. Sexual spores are produced on specialized cells called basidia and are wind dispersed. The basidiospores germinate to form a homokaryotic mycelium which fuses with a compatible homokaryotic mycelium to form the dikaryotic stage (Adaskaveg and Ogawa, 1990).

Uses

P. noxius and other wood decay fungi play an important role in the forest ecosystem as primary decomposers.

Habitat Description

The disease may be found in open places in the primary forest canopy, including areas disturbed by storms, landslides, etc. Most often it is encountered in secondary forests, on land cleared for hardwood plantations, agroforestry, or human habitation. It is less often found in wet, poorly drained soils (Brooks, 2002a).

Reproduction

Sexual reproduction by basidiospores, asexual by fragmentation of mycelium and possibly by arthroconidia (Chang, 1996).

GLOBAL INVASIVE SPECIES DATABASE

FULL ACCOUNT FOR: *Phellinus noxius*

Nutrition

P. noxius is able to metabolize lignin as well as the complex polysaccharides of wood (Adaskaveg and Ogawa, 1990).

General Impacts

Brown root rot is reported as a disease of forest trees in Southeast Asia and the Pacific. It is usually cited, however, for its damage to forest and hardwood plantations, fruit orchards, and landscapes. Mahogany, rubber, hoop pine, and cocoa plantings have been seriously affected. Plantations and orchards cannot be replanted for many years due to the longevity of *P. noxius* in the soil and its broad host range (Brooks, 2002a).

Management Info

Push-heap-and-burn clearing was used in hoop pine plantations in Queensland (Bolland, 1984) to remove infected stumps and some roots. However, remaining diseased roots are an inoculum source until all fungal mycelium is dead. Planting grasses with deep, fibrous root systems may speed up root decomposition. Flooding fields for more than one month may eliminate the fungus (Chang, 1996). When replanting infested areas, space trees as far apart as practical. Rogue out plants with symptoms of yellowing, wilting, or leaf drop as soon as possible.

Pathway

Dispersion is possible through transport of infested soil.
